

A simple J0 Program

```
module M {           // module
    int i;          // global variable
    void foo() {     // function
        int k;        // local variable
        k = 0;
        i = k;
    }
    int inc(int x) {
        return x + i;
    }
    int j;
}
```

J0 Namespaces

A defined name is visible,

- if the declaration is in the same or an enclosing block, and
- if the name is declared textually before.

If there is more than one declaration in the enclosing blocks, then only the innermost declaration is visible.

```
module M {
    int i;
    int foo(int n) {
        if (n > 0) return foo(n - 1); else return i;
    }
    void init() {
        int i;
        i = foo(1);
    }
}
```

J0 Types

J0 offers two built-in primitive types:

- boolean, and
- int.

Furthermore J0 supports one-dimensional arrays of any type; e.g.

- int []
- boolean [] []

J0 Arrays

- Arrays are created with a special form of a variable declaration. Here is a definition of an array of type `int []`:

```
int js[3]; // variable declaration and array creation of  
           // a one-dimensional integer array of length 3
```

- It is possible to define multi-dimensional arrays (arrays of arrays):

```
int ms[3][4]; // defines a 3 x 4 matrix of type int[ ][ ]
```

- The array indices of an array of length n range from 0 to $n - 1$
- An array element can be accessed with the `[...]` operator:

```
int as[3];  
...  
as[2] = as[0] + as[1];
```

- Restriction: it is not possible to assign values of an array type

```
int bs[3];  
bs = as;
```

J0 Functions

- Parameter passing is done

- call-by-value for values of type int and boolean, and
 - call-by-reference for arrays.

```
void setOne(int[ ] xs) { xs[0] = 1; }
void setTwo(int x) { x = 2; }
int run() {
    int ys[1];
    ys[0] = 0;
    setOne(ys);
    setTwo(ys[0]);
    return ys[0];
}
```

- Functions cannot return arrays. The result type of a function can either be void, int or boolean.
- Functions with result type void do not return any result.

Short-Cut Evaluation

- Generally, before executing a binary operation, both operands are evaluated first.
- For the logical operators & and the |, short-cut evaluation is performed; i.e.
 - In expression `e_1 & e_2`, `e2` is only evaluated, if `e1` evaluates to true,
 - in expression `e1 | e2`, `e2` is only evaluated, if `e1` evaluates to false

```
int i;
void bar() { return i < 5; }
int foo(boolean b) {
    i = 0;
    if (b & bar()) return i; else return i + 2;
}
```

What does the function call `foo(false)` return?
